Photocatalytic degradation is an attractive strategy to purify waste water contaminated by macromolecular organics. Compared with the single-component photocatalysts, heterostructures of different semiconductors have been widely used to improve the photocatalytic performance. In this work, we fabricate a hetero-structured photocatalyst consisting of two-dimensional graphitic carbon nitride (g-C₃N₄) nanosheets and commercial MoO₃ microparticles through a simple mixing and annealing process. The photocatalytic performance was evaluated in various dye degradation reactions, especially Rhodamine (RhB) degradation. The MoO₃/g-C₃N₄ composite shown a significant improvement compared with individual MoO₃ or g-C₃N₄ as well as their physical mixture. By applying electron spin resonance (ESR) spin-trap spectra, radical scavenging experiments and electrochemical analysis, we find that a direct Z-scheme charge transfer between MoO₃ and g-C₃N₄ not only causes an accumulation of electrons in g-C₃N₄ and holes in MoO₃, but also boosts the formation of superoxide radical and hydroxyl radical. The superoxide radical and hole dominate the photocatalytic degradation, while the hydroxyl radical plays a negligible role and its production can be suppressed by lowering the pH value.

1. Introduction

Dyes, as colored substances, have been widely used for textile, printing, and paper industries. Due to their high solubility in water and low biodegradability, a direct release of such wastes can lead to serious and long-term pollution of rivers and waterways. A variety of methods have been developed for water purification, such as membrane separation (Liao et al., 2018), physical adsorption (Pu et al., 2017a; Pu et al., 2018), chemical coagulation (Ajuboori et al., 2015), electrochemical (de Araujo et al., 2015) and biological activated sludge process (Grandclement et al., 2017). These methods transfer contaminants from water to another material without degrading them into small and nontoxic molecules, leading to a secondary pollution. Advanced oxidation technology (Merkulov et al., 2018; Pu et al., 2017b; Pu et al., 2017c; Zinatloo-Ajabshir et al., 2017), typically the photocatalytic process (Mahdiani et al., 2018; Salavati-Niasari et al., 2016), produces strong oxidizing radicals under light irradiation and degrade macromolecular organics into small molecules (Zheng et al., 2016).

Graphitic carbon nitride (Wen et al., 2017) as a polymeric two-dimensional layered semiconductor has attracted a great interest since 2009 (Wang et al., 2017). It exhibits high chemical and thermal stability, narrow bandgap (~2.7 eV), and potentially high surface area (after exfoliation), which make it highly attractive in the photocatalytic water splitting (Che et al., 2017; Yan et al., 2009), CO₂ reduction (Shi et al., 2018), N₂ fixation (Ma et al., 2016), and organic contaminant degradation (Dai et al., 2014; Oh et al., 2017). Nevertheless, when used as a single component photocatalyst, the performance of g-C₃N₄ is generally limited by its fast recombination of...
electrons and holes (Zhu et al., 2017). A hybridization of g-C$_3$N$_4$ with a second semiconductor, such as TiO$_2$ (Tong et al., 2015; Wei et al., 2017), Ag$_3$PO$_4$ (Wang et al., 2014), Cds (Fan et al., 2016), BiVO$_4$ (Deng et al., 2018), etc. usually induces a spatial separation of electrons and holes with prolonged lifetimes, thus enhancing the photocatalytic preference.

Molybdenum trioxide (MoO$_3$), as a visible light responsive semiconductor, has been frequently selected to improve the activity of g-C$_3$N$_4$ (Feng et al., 2017; He et al., 2014; Huang et al., 2013; Li et al., 2015; Xie et al., 2018; Zhang et al., 2018a). For instance, a g-C$_3$N$_4$ shell was coated on the surface of MoO$_3$ microparticles to form a conventional Type-II heterojunction (Huang et al., 2013). Under a light irradiation, both semiconductors are excited. The photoelectrons tend to accumulate on the conduction band of MoO$_3$ (more positive) while the holes prefer to concentrate on the valence band of g-C$_3$N$_4$ (more negative), thus lowering the overall redox ability of the hybrid. In contrast, a completely different path, i.e. a Z-Scheme transfer, has been suggested for MoO$_3$/g-C$_3$N$_4$ systems by many other groups (Feng et al., 2017; He et al., 2014; Ma et al., 2017; Patnaik et al., 2018). In that case, the electrons in the conduction band of MoO$_3$ recombine with the holes in the valence band of g-C$_3$N$_4$, and the rest holes and electrons maintain their high redox ability (Zhang et al., 2018a). Although radical scavenger experiments (Feng et al., 2017; Li et al., 2015) and/or ESR spin-trap spectra (Xie et al., 2018; Zhang et al., 2018a) have been adopted to prove the type of charge transfer, a more convincing and comprehensive confirmation of the Z-Scheme transfer and the correlation between charge transfer and radical formation are demanded. Moreover, the role of different radicals in photocatalytic dye degradation still need to be clarify. For instance, ·OH has been regarded as the active radicals in many systems (Liu et al., 2016a; Liu et al., 2016b), including Flg-C$_3$N$_4$/α-MoO$_3$ NNs (Zhang et al., 2018b), yet, negligible activity of ·OH in dye degradation by MoO$_3$/g-C$_3$N$_4$ have also been reported by many other groups based on radical scavange experiments (Liu et al., 2016; Ma et al., 2017; Patnaik et al., 2018; Xie et al., 2018; Zhang et al., 2018a).

In this study, a series of MoO$_3$/g-C$_3$N$_4$ composites with different Mo loadings are prepared through a mixing - annealing method. The combination of MoO$_3$ and g-C$_3$N$_4$ remarkably enhances the photocatalytic activity in dye degradation, compared to pure g-C$_3$N$_4$ and MoO$_3$ as well as a MoO$_3$/g-C$_3$N$_4$ physical mixture. The charge transfer path is studied by applying various techniques, especially ESR spin-trap spectra and radical scavange experiments, and the reactivity of ·OH is carefully addressed.

2. Experimental section

2.1. Materials

Urea was purchased from US Promega Corporation. Isopropanol (C$_3$H$_7$OH, ≥ 99.7%), benzoquinone (C$_6$H$_4$O$_2$, AR grade), triethanolamine (HO(CH$_2$)$_2$OH, ≥ 99.0%), rhodamine B (C$_29$H$_37$ClN$_2$O$_2$, ≥ 95%), methylene blue (C$_{16}$H$_{18}$ClN$_3$S, ≥ 82%), safranine T (C$_{20}$H$_{19}$ClN$_4$, ≥ 80%), and methyl blue (C$_{19}$H$_{18}$N$_2$O$_3$, ≥ 80%), molybdenum(VI) oxide (MoO$_3$, AR grade), sodium sulfate anhydrous (Na$_2$SO$_4$, AR grade), and Nafion (AR grade) were purchased from Sigma-Aldrich Chemical Co (USA). Deionized (DI) water and ethanol were purchased from Sigma-Aldrich (molecular biology reagent). All reagents were used without further purification.

2.2. Preparation of MoO$_3$/g-C$_3$N$_4$ composites

g-C$_3$N$_4$ (CN) was synthesized according to a previously reported method (Li et al., 2018). Typically, 10 g of urea was placed into a 20 mL alumina crucible with a cover, and then it was heated up to 550 °C in a muffle furnace at a ramp of 15 °C min$^{-1}$, and then kept at this temperature for 4 h. After cooling to room temperature, the obtained yellow g-C$_3$N$_4$ was collected and ground for further use.

The MoO$_3$/g-C$_3$N$_4$ composites were prepared by mixing MoO$_3$/g-C$_3$N$_4$ followed by a calcination process (Xie et al., 2018). 4 mg to 17.3 mg of MoO$_3$ and 98 mg g-C$_3$N$_4$, with a target MoO$_3$ loading of 3.9 wt% to 15 wt%, were dispersed into 40 mL of ethanol, then the mixture was sonicated for 1 h and dried at 65 °C under a stirring. The obtained MoO$_3$/g-C$_3$N$_4$ powder was then placed into an alumina crucible with a cover and calcined at 300 °C in air for 4 h in a muffle furnace. The samples were named x-Mo-CN (x = 3.9, 7.5, or 15) for short. A MoO$_3$-g-C$_3$N$_4$ physical mixture with a MoO$_3$ loading of 7.5 wt% was prepared by grinding the powders for 5 min.

2.3. Characterization

X-ray diffraction (XRD) was performed with a PANalytical X’pert MPD Pro at 45 kV and 30 mA, using Cu K$_\alpha$ radiation at a scanning rate of 3° min$^{-1}$ in the 2θ range from 5° to 60°. The morphology of the prepared samples was obtained by scanning electron microscope (SEM) with an FEI XL-30FE (acceleration voltage at 10 kV). Fourier-transform infrared spectroscopy (FTIR) spectra were measured by Nicolet iS50 FTIR Spectrometer in the wavenumber range from 4000 to 500 cm$^{-1}$.

2.4. Photoelectrochemical measurements

Electrochemical measurements was performed in a three-electrode system with a platinum (Pt) wire as the counter electrode, a Ag/AgCl electrode as the reference electrode, and with an aqueous Na$_2$SO$_4$ (0.5 M) as the electrolyte. The working electrode was fabricated through an ink coating process. 10 mg of catalyst was dispersed into 1 mL of ethanol and 20 µL of Nafion. Then the mixture was sonicated for 1 h and magnetically stirred overnight to get a homogeneous ink. Then, 50 µL of the ink was coated onto a 1.0 cm × 1.5 cm fluorine-doped tin oxide (FTO) plate and dried in a muffle furnace at 120 °C for 1 h. A 500 W Xenon lamp equipped with a Newport Solar Simulator AM 1.5G filter was used as the solar simulator.

2.5. Photocatalytic experiment

The photocatalytic RhB degradation was tested under a solar simulator with a power density of 100 mW cm$^{-2}$. 25 mg of catalyst was dispersed into 50 mL of RhB solution (10 mg L$^{-1}$) by sonication, then it was stirred in dark for 30 min to achieve an adsorption–desorption equilibrium. During the test, 2 mL of the suspension was collected at certain time intervals and analyzed with an UV–vis spectrometer (UV-2450, Shimadzu) after removing the solid catalyst by centrifuge. The concentration of RhB was evaluated based on the absorption band peak at around 554 nm.

The methylene blue (MB), safranine T (ST), and methyl blue (Mb) degradation were tested with the same procedures except using
solution of 10 mg L$^{-1}$ and checking the absorption band maximum at 665 nm, 530 nm and 660 nm, respectively.

3. Results and discussion

XRD results are shown in Fig. 1a. The as-prepared CN exhibits two broad peaks at 2$\theta$ of 12.7° and 27.4°, which ascribe to the in-plane structural packing motifs (indexed as (100)) and the interlayer stacking of conjugated aromatic systems (indexed as (002)) (Masih et al., 2017), respectively. The broad peaks suggest a poor crystallinity and/or a limited thickness of the sample. By adding the commercial MoO$_3$, several sharp peaks at 12.9°, 23.4°, 25.7°, 27.3°, 33.8° and 39.1° appear, indicating an orthorhombic structure (JCPDF 35–0609) (Feng et al., 2017) and a bulk feature of the MoO$_3$ particles. The intensity of the MoO$_3$ patterns is enhanced gradually with an increase of the MoO$_3$ content from 3.9 wt% to 15 wt%; meanwhile, the CN patterns are basically maintained.

Fig. 1b shows the FTIR spectra of CN and xMo-CN. All the samples exhibit a broad shoulder at 3300-3000 cm$^{-1}$, which is from the stretching modes of C-OH and/or N-H (Wang et al., 2013). Characteristic peaks of g-C$_3$N$_4$ are present in the range of 1750 e 800 cm$^{-1}$: the strong peaks at 1750-1000 cm$^{-1}$ are ascribed to the emblematic aromatic stretching vibrations of C-N and the typical C=C heterocycles while the peak at 810 cm$^{-1}$ is assigned to the triazine units (Xie et al., 2018). No additional peaks related to MoO$_3$ (i.e. the stretching mode of O=Mo, O-Mo$_2$ and O-Mo$_3$) (Xie et al., 2018) can be detected with a MoO$_3$ loading up to 15 wt%. Noteworthy, the characteristic peaks of g-C$_3$N$_4$ do not show any significant change, indicating a limited effect of the MoO$_3$ micro particles on the molecular structure of g-C$_3$N$_4$.

According to the SEM results, the pristine CN exhibits a porous and lamellar structure (Fig. 51), which is basically maintained after the introduction of MoO$_3$ (Fig. 1c). Micro-sized MoO$_3$ particles (1$\sim$10 µm) can be observed in the 7.5Mo-CN composite with their surface decorated with fluffy g-C$_3$N$_4$ nanosheets (Fig. 1c). However, a significant portion of the nanosheets shows no contact with MoO$_3$ due to the large particle size, small surface area, and limited content of MoO$_3$. HRTEM has also been tested (Fig. 1d). The nanocrystals with lattice spacing of 0.351 nm and 0.196 nm match, respectively, to the (040) and (061) of MoO$_3$ (He et al., 2014; Huang et al., 2013), while the g-C$_3$N$_4$ around them exhibits no lattice fringes. The crystallinity of these two materials are in a good agreement with the XRD results.

BET analysis shows that the addition of MoO$_3$ microparticles leads to a significant decrease of the specific surface area from 138.59 m$^2$ g$^{-1}$ (CN) to 63.27 m$^2$ g$^{-1}$ (7.5 Mo-CN). It is probably caused by the big MoO$_3$ microparticles or by the calcination process.

The surface chemical composition and chemical states are analyzed by XPS. As shown in Fig. 2a, two carbon species are present in both CN and 7.5Mo-CN. The main peak at 288.2$-$288.4 eV is from the N-C=N carbon (Xu et al., 2013) while the small one at 284.8 eV is from the C-C/C=C species (Gao et al., 2017). In terms of N, the three peaks at 398.7 eV, 400.2 eV and 401.3 eV correspond to C-N=C, N-(C)$_3$ and N-H species (Gao et al., 2017), respectively (Fig. 2b). An evident decrease of the N-H and C-N=C species, related to N-(C)$_3$, indicates a removal of edge N atoms after the Mo loading (Huang et al., 2015). Such structural defects have been reported to trap photoelectrons (Zhang et al., 2018a; Zhu et al., 2018). The commercial MoO$_3$ is also analyzed and it displays two doublets at the binding energies of 236.6/233.4 eV and 235.1/232.0 eV, respectively. The main doublet at 236.6/233.4 eV correspond to Mo$^{6+}$ ($\sim$95%), while the latter is ascribed to Mo$^{5+}$ species (He et al., 2014). After the combination with CN, only one doublet exists at
235.9/232.7 eV. Regarding the calcination treatment in air, the Mo in 7.5Mo-CN is proposed to be oxidized to Mo$^{6+}$. The big shift of binding energy to lower values indicates that the MoO$_3$ microparticles are chemically bound with the g-C$_3$N$_4$, thanks to their intimated contact (Xie et al., 2018). As expected, the bonding energy of C in g-C$_3$N$_4$ slightly shifts to the opposite side (i.e. to higher binding energies) after the loading of MoO$_3$. The less shift of C (and N) compared with Mo is probably due to the prevalence of bare g-C$_3$N$_4$ without in contact with the MoO$_3$ microparticles (as confirmed by SEM in Fig. 1c). The XPS-valence bands of CN and MoO$_3$ are evaluated and it turns out a position of 1.83 eV and 3.67 eV, for CN and MoO$_3$, respectively (Fig. 2d).

The optical absorbance properties of CN, MoO$_3$ and 7.5Mo-CN are measured by UV–vis DRS (Fig. 3a). All the three samples show absorption edges at around 450 nm. The bandgaps of CN, 7.5Mo-CN and MoO$_3$, obtained from the Kubelka-Munk plots (Otsuka, 2004), are 2.84, 2.81, and 2.74 eV, respectively (Fig. 3b). Basically, the addition of MoO$_3$ has a very limited impact on the light absorption. The photocatalytic activities of all the samples in RhB degradation are shown in Fig. 4a. In the absence of a photocatalyst, no degradation of RhB is observed under the light irradiation, thus ruling out the self-degradation of RhB. The MoO$_3$ alone shows no activity, while the pure CN degrades more than 60% of the RhB within 25 min. The incorporation of the inactive MoO$_3$ significantly enhances the overall activity, and the RhB can be completely degraded within 10–15 min based on the UV–vis spectra (Fig. S2). A blue shift of absorption peak of RhB solution from 554 nm to 495 nm indicates a N-demethylation process during the degradation of RhB (Liu et al., 2017b). By increasing the content of MoO$_3$ from 0 to 15 wt%, the activity shows a volcano-shaped trend and
7.5Mo-CN performs the best. No evident decay of the RhB degradation rate can be observed during the four-cycle tests (Fig. 4c). The sample before and after test are compared in Fig. S3. Although the g-C3N4 nanosheets curl during the test, their contact with MoO3 particles are well maintained according to SEM (Fig. S3 f). The XRD, FTIR and XPS results do not show any big change, confirming the good stability of 7.5Mo-CN. The reaction kinetics of photocatalytic activity are further calculated for a quantitative comparison. All the results are fitted by first-order model as given by the following equation (Liu et al., 2016).

\[
\ln \left( \frac{C_0}{C} \right) = kt
\]

where \( C_0 \) is the initial concentration of dye, \( k \) is the apparent reaction first-order rate constant, \( C \) is the concentration of the dye after exposure time of \( t \) (Ma et al., 2017). The photocatalytic reaction rate of the samples can be easily compared by the \( k \) values. As shown in Fig. 4b, the reaction rate increases from 0.0424 to 0.1503 and 0.2499 min\(^{-1}\) with the addition of MoO3 from 0% to 3.9 wt% and 7.5 wt%, respectively. A further addition of MoO3 to 15 wt% causes a decrease of the reaction rate to 0.1681 min\(^{-1}\), which is probably due to the shielding of g-C3N4 by MoO3 (Feng et al., 2017).

As a control experiment, a mixture consisting of 7.5 wt% of MoO3 and 92.5 wt% of CN is prepared by physical grinding. The mixture shows small improvement compared with CN, yet its activity is not comparable with 7.5Mo-CN, despite the same composition (Fig. 4a). The results highlight the role of the strong interaction between the two components in building up a synergy. Moreover, despite the negative impact of MoO3 addition in lowering the specific surface area, 7.5Mo-CN still outperforms the original CN. The catalysts have been further applied to other dyes, such as methylene blue (MB), safranine T (ST) and methyl blue (Mb), and in all cases the 7.5Mo-CN performs better (Figs. 4d and S4). Compared with other catalysts, the catalytic activity of the 7.5Mo-CN is better than most of them (Table S1).

### 3.1. Reaction mechanism

Radical scavenge experiments are firstly carried out to understand the active species. Isopropanol (IPA, 75 mM), triethanolamine (TEOA, 10 mM) and p-benzoquinone (p-BQ, 1 mM) are used as the scavengers for \( \cdot \text{OH} \), hole and \( \cdot \text{O}_2 \), respectively (Liu et al., 2017a; Lu et al., 2017). As shown in Fig. 5a, the addition of IPA has a limited impact on the RhB degradation, while the addition of either TEOA or p-BQ largely suppresses the reaction. It indicates a vital role of hole and \( \cdot \text{O}_2 \) in catalyzing the degradation of RhB. To further confirm the existence of \( \cdot \text{OH} \) and \( \cdot \text{O}_2 \) in the system, ESR spin-trap experiment is performed with DMPO as the spin-trapping agent (Liu et al., 2016). As shown in Fig. 5c and (Ye et al., 2016), neither \( \cdot \text{OH} \) nor \( \cdot \text{O}_2 \) is produced in dark, while the light irradiation induces a gradual increase of both radicals in both the CN and 7.5Mo-CN systems (Fig. S5). Regarding the negligible impact of IPA (as a \( \cdot \text{OH} \) scavenger, shown in Fig. 5a), the existence of \( \cdot \text{OH} \) in the system based on ESR proves a low activity of \( \cdot \text{OH} \) in RhB degradation. As a proof of concept, the pH value is adjusted to alter the concentration of \( \cdot \text{OH} \) in the solution. Generally, pH value affects the photocatalytic reaction by changing the surface charge and the adsorption behavior or by changing the generation of radicals (Rosli et al., 2018; Tao et al., 2015). With a decrease of pH value from 11 to 3, the adsorption capacity of 7.5Mo-CN remains constant, ruling out the
former effect, while the photocatalytic activity improves continuously (Fig. 5b). Based on the formation paths of ·OH (i.e. $h^+ + H_2O \rightarrow OH + H^+$ or $h^+ + OH^{-} \rightarrow OH$) (Michael R. Hoffmann, 1995; Wen et al., 2017), a higher pH value favors the conversion of holes to ·OH. To further confirm the effect of pH value on the conversion of holes, quencher experiments with TEOA (hole scavenger) at pH of 3 and 11 are performed (Fig. 5e). In the absence of TEOA, the sample at pH of 3 shows much higher activity than at pH of 11. However, by trapping all the holes with TEOA, the activity at pH of 3 and 11 become similar. Since the activity of hydroxyl radicals is negligible and the degradation of RhB is mainly contributed by holes and superoxide radicals. It is evident that the hole concentration is much higher at pH of 3 than at pH of 11, while the concentration of superoxide radicals does not depend on the pH value. Therefore, the declined activity in basic solutions strongly support our expectation that the produced ·OH are not active for the RhB degradation reaction.

As shown in Fig. 5c–d, 7.5Mo-CN has a higher production efficiency of both radicals compared with CN, in line with its higher photocatalytic activity. To understand this phenomenon, the energy diagram of this heterojunction is prepared. According to bandgaps and the valence band positions, obtained from UV–vis DRS and XPS-VB, respectively, CN has a conduction band of $-1.01$ eV and a valence band of $1.83$ eV, while MoO3 has a conduction band of $0.93$ eV and a valence band of $3.67$ eV (shown in Scheme 1). Generally, ·O2 is produced via a reduction of O2 with the photogenerated electrons ($e^- + O_2 \rightarrow \cdot O_2$), $O_2/ \cdot O_2 = -0.33$ V vs. NHE (Michael R. Hoffmann, 1995; Wen et al., 2017). The conduction band electrons in MoO3 are thermodynamically not active to produce ·O2. Thus, the higher concentration of ·O2 in the 7.5Mo-CN system indicates a better accumulation of electrons in the conduction band of CN, rather than MoO3. In terms of ·OH$, it can be either directly produced by an oxidation of H2O with holes ($h^+ + H_2O \rightarrow OH + H^+$, ·OH/OH$^- = 2.40$ V vs. NHE) (Michael R. Hoffmann, 1995; Wen et al., 2017) or come indirectly from ·O2 through a series of reactions ($O_2 + H_2O \rightarrow H_2O_2 + ·OH$) (Michael R. Hoffmann, 1995; Wen et al., 2017). Since the valence band of g-C3N4 (i.e. $1.83$eV) is not positive enough to produce ·OH$^-$ directly, the ·OH$^-$ observed in the pure CN system (Fig. 5d) should be produced through the indirect path. The significantly higher concentration of ·OH in the presence of MoO3 (i.e. for the 7.5Mo-CN system) is due to a change of the reaction path, i.e. to a direct oxidation of H2O by the highly oxidative holes in the valence band of MoO3 ($h^+ + H_2O \rightarrow ·OH + H^+$). To summarize, the accumulation of electrons in the conduction band of CN while holes in the valence band of MoO3 highly suggests a Z-Scheme type charge transfer (Zhang et al., 2018a)(Scheme.1a). Under the light irradiation, both MoO3 and g-C3N4 are excited. The photoelectrons in the conduction band of MoO3 tend to recombine with the holes in the valence band of g-C3N4, thanks to the small gap (i.e. $0.90$ eV). The left electrons in the conduction band of g-C3N4 are relatively stable thus continuously reduce O2 to ·O2. The holes in the valence band of MoO3 partially contribute to the oxidation of dyes, while the rest holes are converted to ·OH, which however is not reactive for RhB. In term of a conventional Type-II heterojunctions, the charge transfer from the high energy conduction band and valence band to the lower energy ones will lead to a decline of both ·O2 and ·OH concentrations (Scheme.1b), which however is not the case of our system.

Photoelectrochemical experiments are conducted to investigate the formation, separation and transfer of the photocarriers (Guo et al., 2018). As shown in Fig. 6a, the two samples show stable photocurrent under light illumination, and the photocurrent intensity of 7.5Mo-CN is ~1.8 times higher than CN, indicating a boost of photocarriers with the addition of MoO3. The electrochemical
impedance spectroscopy (EIS) measurements (Fig. 6b) give a smaller diameter of the semicircular Nyquist plot for 7.5Mo-CN, suggesting a lower charge transfer resistance. Despite the imperfection of the selected commercial MoO3 microparticles in terms of their large sizes and limited interface with the g-C3N4 nanosheets, the partially formed heterostructure still effectively separate the photoexcited electron-hole pairs and enhance the photocatalytic activity.

4. Conclusions

In summary, a series of MoO3/g-C3N4 hetero-structured photocatalysts have been prepared by a mixing - annealing method, which results in a strong interaction between the two components as well as a synergistic effect in the photocatalytic dye degradations. The photocatalytic enhancement is caused by a direct Z-scheme interparticle charge transfer, which not only facilitates the separation of electron-hole pairs but also thermodynamically favors the formation of active O2 radicals and holes. This research provides a more convincing and comprehensive certificate of the charge transfer path in the MoO3/g-C3N4 system by applying the ESR spin-trap spectra, radical scavenge experiments, photoelectrochemical analysis and so on. It builds up a correlation between the charge transfer paths and the radical formations and proves the poor reactivity of •OH in RhB degradations. In addition, the work provides a concept to control the formation of active radicals by properly designing the heterostructures and by changing the reaction conditions, such as pH value.
